ABSTRACT

We propose a scenario for the formation of DA white dwarfs with very thin helium buffers. For these stars we explore the possible occurrence of diffusion-induced CNO-flashes, during their early cooling stage. In order to obtain very thin helium buffers, we simulate the formation of low mass remnants through an AGB final/late thermal pulse (AFTP/LTP scenario). Then we calculate the consequent white dwarf cooling evolution by means of a consistent treatment of element diffusion and nuclear burning.

Based on physically sounding white dwarf models, we find that the range of helium buffer masses for these diffusion-induced novae to occur is significantly smaller than that predicted by the only previous study of this scenario. As a matter of fact, we find that these flashes do occur only in some low-mass ($M \lesssim 0.6M_{\odot}$) and low metallicity ($Z_{\text{ZAMS}} \lesssim 0.001$) remnants about $10^6 - 10^7$ yr after departing from the AGB. For these objects, we expect the luminosity to increase by about 4 orders of magnitude in less than a decade. We also show that diffusion-induced novae should display a very typical eruption lightcurve, with an increase of about a few magnitudes per year before reaching a maximum of $M_V \sim -5$ to -6 . Our simulations show that surface abundances after the outburst are characterized by $\log N_{\text{H}}/N_{\text{He}} \sim -0.15 \dots 0.6$ and $N_{\text{C}} > N_{\text{O}}$ by mass fractions. Contrary to previous speculations we show that these events are not recurrent and do not change substantially the final H-content of the cool (DA) white dwarf.

Finally, with the aid of model predictions we discuss the possibility that Nova Vul 1670 (CK Vul) and the recently proposed [WN/WC]-central stars of planetary nebulae could be observational counterparts of this diffusion-induced nova scenario. We conclude that, despite discrepancies with observations, the scenario offers one of the best available explanations for CK Vul and, with minor modifications, explains the observed properties of [WN/WC]-central stars of planetary nebulae.

Key words: stars: AGB and post-AGB –stars: individual: CK Vul, PB8 –stars: Wolf Rayet – white dwarfs.

1 INTRODUCTION

It is well known that element diffusion plays a major role in shaping the chemical stratification of white dwarfs (Koester & Chanmugam 1990). Gravitational settling is responsible for the chemical purity of the outer layers of white dwarfs. Due to the very high surface gravities of these stars the lightest element remaining in the white dwarf (either H or He) floats up and forms a pure envelope, the thickness of which gradually increases as the white dwarf evolves. On the other hand, the large chemical gradients formed dur-

ing the previous evolution, lead to chemical diffusion which, in turn, will smooth out the chemical profile of cool white dwarfs (e.g. Renedo et al. 2010). Recently, the gravitational settling of ^{22}Ne in the liquid interior of white dwarfs, has been found to be a key ingredient to explain the cooling age of the old, metal-rich, open cluster NGC 6791 (Althaus et al. 2010, García-Berro et al. 2010).

Since the first simulations of white dwarf evolution that included a simultaneous treatment of diffusion and cooling (i.e. Iben & MacDonald 1985, 1986) it was noticed that diffusion could trigger thermonuclear CNO-flashes. In fact, the inward diffusion of H and the outward diffusion of C within the pure He zone that is located below the H-rich envelope

* E-mail: mmiller@fcaglp.unlp.edu.ar

and above the C-rich intershell (usually named “He-buffer”, see Fig. 1) can lead to a runaway CNO-burning. This possibility was shown by Iben & MacDonald (1986) who found that, if the He-buffer was thin enough, C and H can come into contact and develop an unstable H-burning. This sudden energy release produces a very rapid expansion, of the order of years, of the outer layers of the white dwarf pushing the star back to a giant configuration and increasing its visual magnitude from $M_V \sim 9$ to $M_V \sim -6$ in a few years. We term this eruptive event as “diffusion-induced nova”¹ (DIN) although it leads to a much slower brightening than classical novae. Iben & MacDonald (1986) showed that after such events the stars will become, in a few years, yellow giants with mildly He-enriched surface compositions. In a more speculative mood they also suggested that DINs may be recurrent, finally leading to H-deficient compositions. Later, prompted by this speculation, D’Antona & Mazzitelli (1990) suggested that the H-rich envelope could be strongly reduced during these events, leading to DA white dwarfs with thin H-envelopes, as inferred in some DA white dwarfs (Castanheira & Kepler 2009).

Since the first exploratory simulation performed by Iben & MacDonald (1986), these DINs have been mentioned in several review papers and books (D’Antona & Mazzitelli 1990, Iben 1995, Hansen 2004, Salaris & Cassisi 2005 and more recently Althaus et al. 2010), but no new numerical experiments have been performed. The latter becomes particularly relevant in light of the criticism made by Mazzitelli & D’Antona (1986) that the pre-white dwarf models adopted by Iben & MacDonald (1985) and Iben & MacDonald (1986) were not realistic enough. In this context, a reexamination of the possibility and characteristics of DINs is in order.

As mentioned, DINs are expected to increase their visual magnitudes from $M_V \sim 9$ to $M_V \lesssim -5$ in a few years. Iben & MacDonald (1986) mentioned that such event would display a lightcurve similar to that of a very slow nova. The most famous object with such description is the enigmatic Nova Vul 1670 (CK Vul), the oldest catalogued nova variable (Trimble 2000). First discovered by Père Dom Anthelme the 20th of June of 1670, and later independently by Johannes Hevelius on the 25th of July, seem to have raised to 3rd magnitude in less than a year (Shara et al. 1985), although no pre-maximum observations exist. Its eruption lasted for two years (1670-1672). During that period it faded and brightened two times before definitely disappearing from view. Three centuries later, Shara & Moffat (1982) partially recovered the remnant. They discovered several nebulosities that were conclusively linked to the 1670 eruption by Hajduk et al. (2007) through proper motion studies. CK Vul remains a very enigmatic object and several scenarios have been proposed to explain its observed behaviour. In fact, it has alternatively proposed to be an hibernating nova, a very late thermal pulse (VLTP), a “gentle” supernova, a light nova and a stellar merger event (Hajduk et al.

2007, Kato 2003). None of the proposed scenario seems to correctly describe the observations (Hajduk et al. 2007), although the VLTP seems to be the preferred one (Harrison 1996, Evans et al. 2002 and Hajduk et al. 2007). In this context, and due to the similarities between post-VLTP evolution and post-DIN evolution, it seems worth analysing whether CK Vul could be understood within the DIN scenario.

The main purpose of the present article is to study the possibility that DINs could take place in physically sounding white dwarf models with a realistic evolutionary history. We will also identify a detailed scenario for the creation of white dwarfs with thin enough He-buffers for DIN events to occur. Specifically, to perform this study we compute realistic white dwarf models by means of “cradle to grave” stellar evolution simulations. Then we compute white dwarf cooling sequences by considering a simultaneous treatment of element diffusion and evolution.

The article is organized as follows. In the next section we briefly describe the input physics adopted in the present simulations. Then, in section 3, we identify a possible evolutionary scenario that can lead to white dwarfs with thin He-buffers. Once the evolutionary scenario has been set we present our numerical simulations and results (Section 4). In particular, we show that the proposed scenario can effectively produce white dwarf models with thin He-buffers. Then, we discuss the main predictions of the simulations and explore under which conditions DINs might occur. Furthermore, we make a very detailed description of the sequence of events before, during and after the DIN events. Once the predictions of DIN simulations have been clarified, in Section 5 we look for possible observational counterparts of these events. In particular, we speculate that DINs could be the origin of CK Vul and PB8 (the prototype of the recently proposed [WN/WC]-CSPNe, see Todt et al. 2010) and show that, although significant discrepancies exist, the DIN scenario offers a possible explanation for these objects. Finally, we close the article with some final statements and conclusions.

2 BRIEF DESCRIPTION OF THE STELLAR EVOLUTION CODE

The simulations presented here have been performed with `LPCODE` stellar evolution code (see Renedo et al. 2010). `LPCODE` is a well tested and amply used evolutionary code that is particularly appropriate to compute realistic white dwarf structures and their evolution by means of “cradle to grave” stellar evolution simulations, and allows for a consistent and detailed computation of the effects of element diffusion during the white dwarf cooling phase. As this work is aimed at exploring the outburst properties of diffusion-induced CNO-flashes on hot white dwarfs, it is worth mentioning that `LPCODE` has been previously used to study other kind of H-flashes on (very) hot white-dwarfs. These include the simulations of the post-AGB born again scenario (Miller Bertolami & Althaus 2007), and the post-RGB hot-flasher scenario (Miller Bertolami et al. 2008) for the formation of H-deficient white dwarfs and subdwarfs respectively. Numerical and physical aspects of `LPCODE` can be found in Althaus et al. (2005). In what follows we only comment on

¹ Iben & MacDonald (1986) named these events self-induced novae, but we will use the term “diffusion-induced novae” to distinguish them from late helium flashes (born again AGB stars, Iben 1984) which predict similar lightcurves and can also be considered “self-induced”.

Figure 1. Sketch of a Kippenhahn diagram of the proposed scenario for the formation of DA white dwarfs with thin He-buffers.

the physical inputs regarding the treatment of diffusion processes that are specifically relevant for the present work.

White dwarf models are obtained as the result of computing the evolution of low mass stars from the ZAMS through the helium core flash and through the thermal pulses on the AGB (TP-AGB) and, then, to the white dwarfs stage. LPCODE considers a simultaneous treatment of non-instantaneous mixing and burning of elements, by means of a diffusion picture of convection coupled to nuclear burning —see Althaus et al. (2005) for numerical procedures. The nuclear network considered in the present work accounts explicitly for the following 16 elements: ^1H , ^2H , ^3He , ^4He , ^7Li , ^7Be , ^{12}C , ^{13}C , ^{14}N , ^{15}N , ^{16}O , ^{17}O , ^{18}O , ^{19}F , ^{20}Ne and ^{22}Ne , together with 34 thermonuclear reaction rates corresponding to the pp-chains, the CNO bi-cycle, He-burning and C-ignition as described in Miller Bertolami et al. (2006).

As mentioned in the introduction, element diffusion strongly modifies the chemical profiles throughout the outer layers of white dwarfs. In this work white dwarf evolution was computed in a consistent way with the changes of chemical abundances as a consequence of diffusion. The treatment is similar to that of Iben & MacDonald (1985, 1986) but we consider, in addition to gravitational settling and chemical diffusion, the process of thermal diffusion. We do not take into account radiative levitation, as it is only relevant for determining surface chemical abundances and, thus, is irrelevant for the purpose of the present work. Our treatment of time-dependent element diffusion is based on the multi-component gas picture of Burgers (1969). Specifically, we solved the diffusion equations within the numerical scheme described in Althaus et al. (2003).

3 THE EVOLUTIONARY SCENARIO

The formation of a WD with a very thin He-buffer seems to be a key factor in the occurrence of a DIN episode (see Iben & MacDonald 1986). Iben & MacDonald (1986) obtained a pre-white dwarf model with a thin He-buffer by abstracting mass from an AGB star model shortly after it has experienced a He-flash. Mazzitelli & D’Antona (1986)

noted that the way this pre-white dwarf model was created is artificial and could affect the thermal properties of the remnant. Whether white dwarfs with thin He-buffer can be actually formed relies on identifying a scenario in which they could be formed under standard assumptions. As shown in Fig. 1, after a He-shell flash on the TP-AGB, the mass of the He-buffer region becomes strongly reduced by intershell convection. Such thin He-buffer survives until the reignition of the H-burning shell. Note that this may not be true if the star experiences third dredge up events, during which the deepening of the H-rich envelope will erase the remaining He-buffer by diluting it into the envelope. From this moment on, the He-buffer mass starts to increase until the next He-shell flash. In this context, a realistic scenario that can lead to a DA white dwarf with a thin He-buffer can be outlined. Recent studies on the initial-final-mass relation (Kalirai et al. 2008, Salaris et al. 2009) support the absence of significant third dredge up in low-mass stars (Karakas 2003). In particular, the first thermal pulses of low-mass stars ($M \lesssim 1.5M_{\odot}$) are not very strong and, thus, no third dredge up takes place in numerical models. Hence, it is not unreasonable to accept that low-mass stars experiencing an AGB final thermal pulse (AFTP) or a Late Thermal Pulse (LTP) will end as DA white dwarfs with thin He-buffers. In those cases, as no third dredge up happens, the very thin He-buffer survives the last helium shell flash (either AFTP or LTP). Then, during the He-burning phase that follows the flash, AGB winds will erode an important fraction of the remaining (already depleted) H-rich envelope, preventing a reignition of the H-burning shell and an increase in the He buffer mass. As a result, the He-buffer is still very thin when the star finally reaches the white dwarf phase. We propose that this scenario can lead to white dwarfs with thin He-buffers and therefore might lead to DINs.

In order to bear out the scenario described in the preceeding paragraph we have computed several sequences from the ZAMS to the TP-AGB under standard assumptions —see Renedo et al. (2010) for a description. Particularly, we have included overshooting only in core convective zones within a diffusive convective picture as in Miller Bertolami & Althaus (2006). Thus, no overshooting mixing has been included during the TP-AGB evolution of any sequence, as it leads to strong third dredge up episodes in low-mass AGB stars. Although the efficiency of third dredge up on AGB stars is clearly not a solved problem, it is clear that third dredge up is less efficient in low mass stars than in the more massive stars (e.g. Karakas et al. 2002). In this connection, Salaris et al. (2009) have shown that strong third dredge up is disfavoured, by the semiempirical initial final mass relation, for stars with masses lower than $4M_{\odot}$. It is worth noting that their study only deals with stars of masses $M > 2M_{\odot}$ and can not be directly applied to our work. However, as third dredge up efficiency is expected to decrease for stars of lower masses, it seems safe to assume that no third dredge up should be present in stars of even lower masses. In agreement with this, Guandalini et al. (2006) have suggested that the properties of carbon stars can be explained if no overshooting is added in low mass AGB stellar models. It must be noted, however, that both Salaris et al. (2009) and Guandalini et al. (2006) deal with stars of higher metallicities than studied in the present work and third dredge up is expected to increase at lower metallicities. The absence of

Figure 2. HR-diagram evolution of an initially $0.85M_{\odot}$ star with $Z = 1 \times 10^{-4}$. It undergoes its final thermal pulse on the AGB with a thin envelope and consequently no important H-reignition takes place before reaching the white dwarf cooling stage. This produces a white dwarf with a very thin He-buffer which experiences a DIN due to the diffusive mixing of C and H in the He-buffer (see Fig. 3). Time has been chosen to be $t = 0$ at the point of maximum energy release by H-burning during the CNO-flash.

third dredge up episodes in low-mass AGB stars is of special importance for the scenario outlined in the previous paragraph, as third dredge up erodes the thin He-buffer formed just after a thermal pulse. It is worth noting that mass-loss rates during the RGB and AGB phases have been adopted according to the prescriptions of Schröder & Cuntz (2005) and Vassiliadis & Wood (1993). This choice, together with the absence of third dredge up, is expected to produce a realistic initial final mass relation. The only exception is mass loss just before the final helium flash, which was tuned to obtain an AFTP/LTP episode according to the scenario proposed here. It is worth mentioning that standard AGB winds has been adopted during the He-burning phase *after* the last helium flash (AFTP/LTP), when the star becomes a born again AGB star. No mass loss has been adopted during the high temperature (T_{eff}) phase of pre-white dwarf evolution.

4 RESULTS

In the previous section, we mentioned that several sequences have been calculated for the present study. As all our DIN sequences display similar characteristics, we will first describe the evolution of a chosen reference sequence. Then, we will discuss how differences in progenitor/remnant masses, initial metallicities and He-buffer thicknesses may affect the course of evolution. In particular, we will show in later subsections the range in the predicted abundances and timescales of all

our computed sequences, as well as the characteristics of those sequences that did not undergo DIN episodes.

4.1 Detailed description of a reference sequence

The evolution of our reference sequence in the HR-diagram is shown in Fig. 2. It corresponds to an initially $M = 0.85 M_{\odot}$ (ZAMS) model star with $Z = 0.0001$. After evolving through the central H- and He- burning, the star starts climbing the early AGB. This is so until the development of the first thermal pulse ($t_{\text{age}} = 11757.6$ Myr, $M = 0.584M_{\odot}$), which marks the beginning of the TP-AGB phase. The mass of the hydrogen-free core at that point is $M_{\text{HFC}} = 0.515M_{\odot}$. Due to the low mass of the star at the beginning of the TP-AGB, and owing to the relatively high winds ($\dot{M} \sim 10^{-7}M_{\odot}/\text{yr}$) the star suffers during the TP-AGB and the long interpulse period ($P \sim 530000$ yr), the star experiences only 3 thermal pulses. Mass loss during the very end of the TP-AGB was tuned for the last thermal pulse to develop when the star was just leaving the AGB (an AGB final thermal pulse; AFTP). The mass at the moment of the AFTP is $M = 0.54403M_{\odot}$ with a hydrogen-free core mass of $M_{\text{HFC}} = 0.53839M_{\odot}$. After winds have reduced the mass of the star to $0.53946M_{\odot}$, the star leaves the AGB ($T_{\text{eff}} \gtrsim 10000\text{K}$) and evolves towards the white dwarf stage with a H-envelope of

Figure 3. Evolution of the chemical profiles of our reference sequence ($0.53946 M_{\odot}$). Panels A, B, and C correspond to the instants denoted by the same letters in Fig. 2. Dashed lines in the middle panel indicate profiles just after the development of the convective zone driven by the H-flash.

Figure 4. Predicted lightcurves for the DINs of remnants coming from an initially $M = 0.85 M_{\odot}$, $Z = 0.0001$ star. Different remnant masses were obtained by altering the wind intensity during the AGB final thermal pulse. Visual magnitudes were obtained from the predicted luminosity of the sequences and adopting the bolometric corrections derived by Flower (1996).

$M_{\text{env}}^{\text{PRE-WD}} = 1.07 \times 10^{-3} M_{\odot}$,² which corresponds to a total H-content of $M_{\text{H}}^{\text{PRE-WD}} = 6.6 \times 10^{-4} M_{\odot}$, and a He-buffer thickness of only $M_{\text{Buffer}}^{\text{PRE-WD}} = 1.37 \times 10^{-4} M_{\odot}$. Before entering the white dwarf stage H is reignited, this produces the kink in the HR-diagram (see Fig. 2) just before the point of maximum T_{eff} . As a consequence of this reignition, both the mass of the H-envelope and the total H-content of the star are diminished to $8.5 \times 10^{-4} M_{\odot}$ and $4.2 \times 10^{-4} M_{\odot}$, respectively. Conversely, the mass of the He-buffer zone is increased up to $M_{\text{Buffer}} = 4.38 \times 10^{-4} M_{\odot}$. At this point the sequence begins its cooling as a white dwarf with a thin He-buffer see (Fig. 2). The chemical profile at that point is shown in Fig. 3 (panel A). From that point onwards, the star cools and contracts as a white dwarf. Simultaneously, chemical profiles are altered by element diffusion. In particular, H from the envelope and C from the intershell region, just below the He-buffer (see Fig. 1), diffuse through the He-buffer due to chemical diffusion triggered by the steep chemical profiles left by the previous evolution. Fig. 3 (panel B) shows the chemical profile 7.58×10^6 yr after the white dwarf started its cooling evolution. At this point the amount of C and H diffused into the He-buffer and, consequently the rate of energy generated by CNO burning starts to increase. From this point onwards CNO burning increases slowly until $\log L_{\text{H}}/L_{\odot} \sim 1.5$ when the rate of energy generated by CNO burning leads to the development of convection (about 23000 yr after CNO burning started to increase). This convective zone drags H from regions with higher H mass fractions and thus leads to higher energy generation rates. As a consequence the star enters a quicker phase and in less than 200 yr L_{H} rises to $\log L_{\text{H}}/L_{\odot} \sim 7.5$. This sudden energy injection causes a very quick expansion of the layers on top of the H-burning shell and the star is balloned back to the giant branch in a few years (see Fig. 2). In Fig. 4 we show the predicted visual lightcurve for the outburst episode $-t = 0$ denotes the instant of maximum energy release by the CNO-flash, panel C of Fig. 3, see also Fig. 2. Visual magnitudes have been obtained from the predicted luminosity of the sequences and adopting the bolometric corrections derived by Flower (1996) for normal H-rich abundances. As can be seen after suddenly rising from $M_V \sim 9$ to $M_V \sim 2$ the star increases its visual magnitude much slower than a classical nova, at a speed of $\sim 1^{\text{m}}/\text{yr}$. Specifically, the brightening speed just before reaching its maximum (at $M_V \sim -5.2$, ~ 8 years after the H-flash) is $dM_V/dt \sim 1.6^{\text{m}}/\text{yr}$. Just after the maximum energy release by the H-flash, when the star moves to low temperatures and luminosities, the convective region driven by the H-flash merges with the (very thin) external convective region caused by low temperature opacity. Then, the material from the very outer layers of the star is mixed with the material of the flash-driven convective region. Consequently, the surface abundances of the model are altered. The amount of He rises significantly ($X_{\text{He}} = 0.61$ by mass fraction) while the H mass fraction is reduced ($X_{\text{H}} = 0.39$). Then, the DIN gives rise to an object with a mild H-deficiency. Also N is increased at the surface of the star. As the inner regions, which have experienced CNO burning, are N-enhanced, the surface abundance of N during

² We define the H-envelope as those regions with a H-content greater than 1×10^{-4} by mass fraction.

Figure 5. Evolution of the total H-content of our reference white dwarf sequence. The solid line shows the evolution in the case that AGB-like winds are considered during the second AGB phase after the CNO-flash, while the dashed line indicates the evolution of the H-content in the case no AGB-like winds have been considered. Note that regardless the intensity of winds in this stage the final H-content of the DA white dwarf is not modified and of the order of $M_H \sim 5 \times 10^{-5} M_\odot$.

the outburst increases to 2.2×10^{-4} , significantly higher than the mass fractions of C and O (1×10^{-5} and 1.1×10^{-6} , respectively), and higher than the surface N abundance before the outburst ($N \sim 1.56 \times 10^{-5}$). Once back at low effective temperatures the star is expected to undergo strong winds similar to those of AGB stars. The time spent at low effective temperatures during this stage will be strongly dependent on mass loss assumptions. If standard AGB mass loss is assumed then the star reheats back to $T_{\text{eff}} \gtrsim 10\,000\text{K}$ in about ~ 50 yr, while in the case of no significant mass loss the star stays at low effective temperature for about ~ 260 yr. Under the assumption of standard AGB mass loss, the total mass lost by the object before it starts to contract again is of $1.6 \times 10^{-4} M_\odot$ (see Fig. 5). Finally the star returns to the white dwarf cooling track. The model returns to its pre-outburst stage ($\log L/L_\odot \sim -0.25$ and $\log T_{\text{eff}} \sim 4.6$) in only $\sim 10^5$ yr, much faster than in its pre-outburst cooling, which took $\sim 7.6 \times 10^6$ yr. This should not be a surprise as only the outer layers are affected by the eruption and, so, the interior of the white dwarf still resembles the structure prior to the eruption (see Fig. 6). Only the outer layers, which have much shorter thermal timescales, cool and contract during this second white dwarf stage. The main consequence of this fast cooling is that diffusion has not enough time to alter the composition of the inner regions of our new white dwarf at high effective temperatures and the luminosity of the CNO-burning shell remains very low. Then, no new CNO-flash does take place this second time.

4.2 Dependence on physical and numerical parameters

In order to understand to what extent the outburst properties depend on the remnant properties, we have performed several simulations under different assumptions. Specifically, we have calculated the outburst for remnants of different

masses and also for remnants coming from progenitors of different masses. We also explore how thin the He-buffer needs to be in order to obtain a DIN. The latter is an important issue to understand how frequent these events might be.

To assess the importance of the He-buffer thickness for the development of DIN, we have computed four additional sequences by shutting down winds in our reference sequence at different times immediately after the maximum of He-burning, during the final thermal pulse. Then, the remnant leaves the AGB with thicker H-rich envelopes (and slightly different final masses). As a consequence, when these remnants contract towards the white dwarf stage, the reignition of H leads to thicker He-buffers. Hence, we are able to follow the cooling of white dwarfs with different He-buffer thicknesses (see Table 1). Interestingly enough, the H-envelope mass of the white dwarf is mostly dependent on the metallicity and not on the detailed treatment of mass loss.

As shown in Table 1 all the remnants derived from our $0.85 M_\odot$ $Z = 0.0001$ sequence, reach the white dwarf stage with very similar H-rich envelopes (within a $\sim 10\%$ difference in mass). This is because the H-rich envelope of white dwarfs is mostly dependent on the mass of the remnant and initial metallicity. On the other hand, remnants display significantly different He-buffers thicknesses (with differences up to a factor 5). As a consequence of this difference, the CNO-flash develops at different points (luminosities) in the white dwarf cooling track. In fact, the thicker the He-buffer, the longer time needed for diffusion to mix enough H and C in the He-buffer and trigger the CNO-flash (see Table 2). Also, we find that in our $0.85 M_\odot$ $Z = 0.0001$ sequence, if the He-buffer mass is $M_{\text{Buffer}} \gtrsim 2.1 \times 10^{-3} M_\odot$ the sequence does not experience a DIN. In Fig. 4 we show the lightcurves computed for these sequences. In Table 3 we show the expected abundances for major chemical elements at the surface of the star during the nova outburst. As mentioned in the previous section, the mixing of material from the He-buffer with that at the H-rich envelope by convection, leads to an enhancement of the surface abundances of He and N at the expenses of the H abundance. Depending on the relative masses of the He-buffer and the H-rich envelope the outcome of such mixing gives different values of H, He and N. In fact, for those sequences with thicker He-buffers, the amount of He mixed during the CNO-flash is higher. This can be clearly appreciated from both Tables 1 and 2: the remnants that enter the white dwarf stage with relatively thicker He-buffers are those who end with larger He-abundances after the eruption. In all the cases, however, only a mild ($\log N_{\text{H}}/N_{\text{He}} \approx -0.15 \dots 0.6$) He-enrichment is attained. It is worth mentioning that the amount of H burnt during the nova event is not significant and the star will ultimately end as a H-rich white dwarf (DA white dwarf).

In order to explore to which extent the mass of the remnant and its previous evolution would be relevant for the properties of DIN events, we have calculated additional sequences for different progenitor stellar masses. As in the case of our reference sequence, we have evolved these sequences from the ZAMS up to the AGB phase and tuned mass loss during the last thermal pulse in order to obtain a final thermal pulse when the H-envelope mass was already very thin (i.e. an AFTP/LTP). Again, as it happens with our reference sequence, (standard AGB) winds during

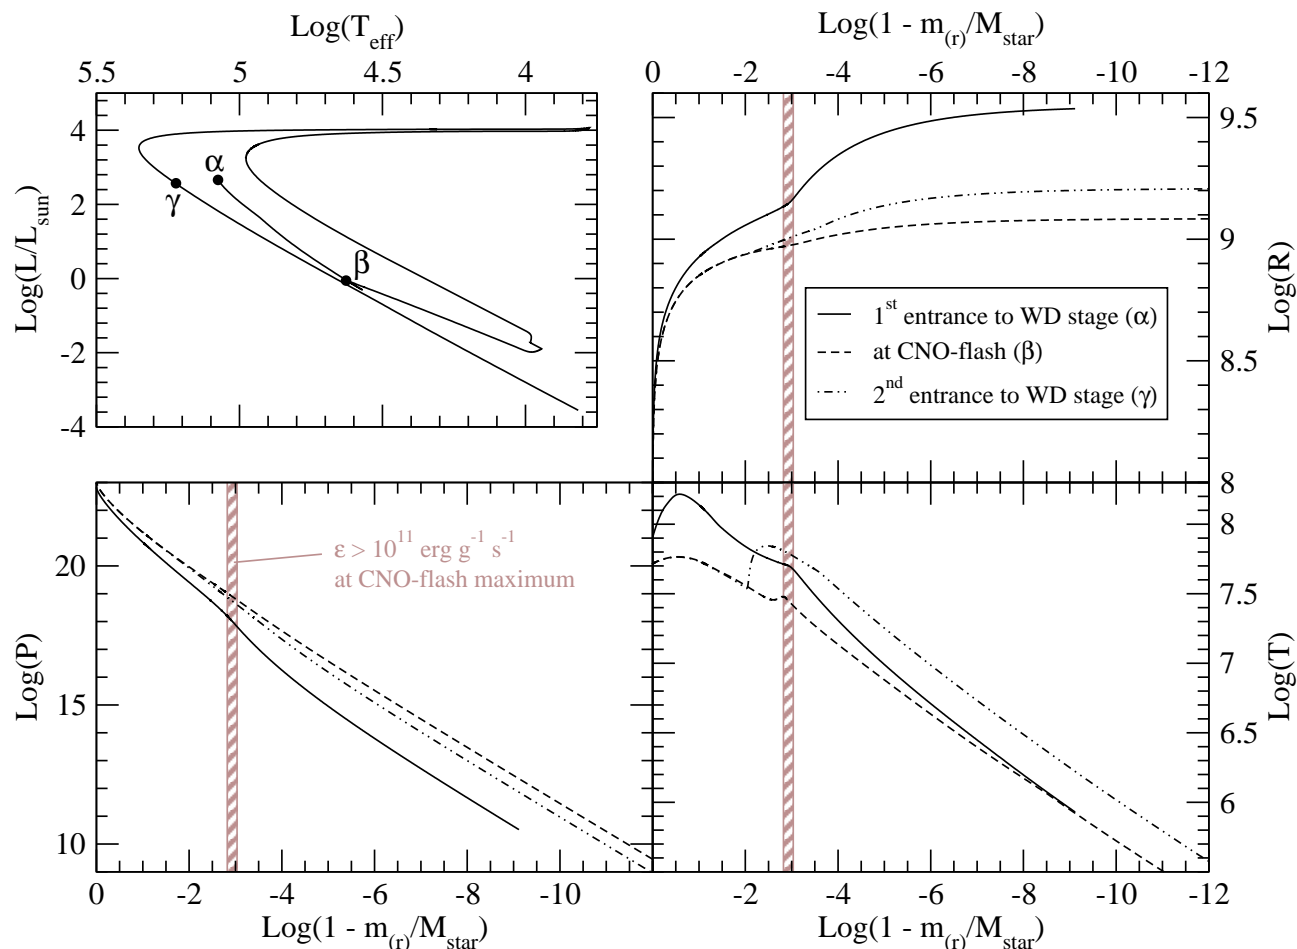

Figure 6. Structure variables ($P(m)$, $T(m)$ and $r(m)$) at three different stages (α , β and γ see upper left panel) of the white dwarf evolution. Note that the interior ($\log(1 - m/M_\star) > -3$) structure of the white dwarf just before (β) and after (γ) the flash is almost unchanged.

the AFTP/LTP erode a significant fraction of the remaining H-envelope, inhibiting an important reignition of the H-burning layer. Thus, white dwarfs with very thin He-buffers are obtained. Namely, we have performed 3 additional cradle to grave sequences with $Z = 0.0001$ and ZAMS masses of $M = 1M_\odot$; $1.25M_\odot$ and $1.8M_\odot$. These sequences end as white dwarfs with thin-He buffers and masses of $0.55156M_\odot$ ($M_H = 2.1 \times 10^{-4}M_\odot$; $M_{\text{Buffer}} = 3.6 \times 10^{-3}M_\odot$), $0.59606M_\odot$ ($M_H = 2.8 \times 10^{-4}M_\odot$; $M_{\text{Buffer}} = 9.8 \times 10^{-5}M_\odot$) and $0.70492M_\odot$ ($M_H = 1.8 \times 10^{-5}M_\odot$; $M_{\text{Buffer}} = 5.9 \times 10^{-5}M_\odot$). While the first two sequences suffered a DIN (see Table 2 for their outburst properties), the last (more massive) one did not. In fact in order to explore how robust this result was, we have followed a similar approach than we did with our reference sequence. By tuning the amount of mass lost during the very last AGB phase, we obtained white dwarfs with very similar masses but significantly different He-buffers and H-contents, namely: $0.70492M_\odot$ ($M_H = 1.8 \times 10^{-5}M_\odot$; $M_{\text{Buffer}} = 5.9 \times 10^{-5}M_\odot$), $0.70496M_\odot$ ($M_H = 4.3 \times 10^{-5}M_\odot$; $M_{\text{Buffer}} = 5.9 \times 10^{-5}M_\odot$), $0.70500M_\odot$ ($M_H = 7.5 \times 10^{-5}M_\odot$; $M_{\text{Buffer}} = 8 \times 10^{-5}M_\odot$), $0.70540M_\odot$ ($M_H = 6.2 \times 10^{-5}M_\odot$; $M_{\text{Buffer}} = 4.8 \times 10^{-4}M_\odot$). In any of these sequences did we obtain a DIN. Thus it seems that DINs do not oc-

cur in white dwarfs with masses significantly higher than the canonical $0.6M_\odot$ value. To explore further the importance of the white dwarf mass for the development of DINs we computed additional sequences by artificially stripped mass during the fifth thermal pulse of our $1.8M_\odot$ sequence³ to obtain a $0.62361M_\odot$ white dwarf with a thin He-buffer ($M_H = 2.6 \times 10^{-4}M_\odot$; $M_{\text{Buffer}} = 7.5 \times 10^{-5}M_\odot$). This sequence did experience a DIN and its properties are described in Table 2.

For the sake of completeness we have also performed two additional full sequences with progenitors of $M = 1M_\odot$ but two different metallicities; $Z = 0.001$ and $Z=0.01$. These sequences end as white dwarfs of $0.55809M_\odot$ ($M_H = 2.9 \times 10^{-4}M_\odot$; $M_{\text{Buffer}} = 2.8 \times 10^{-4}M_\odot$) and $0.52382M_\odot$ ($M_H = 2.5 \times 10^{-4}M_\odot$; $M_{\text{Buffer}} = 5.5 \times 10^{-4}M_\odot$). The first sequence did experience a nova event (see Table 2), while the second one did not.

Although the exploration of the parameter space we have made is not completely exhaustive, we can draw some preliminary conclusions. To begin with, it seems that the

³ Under standard AGB winds the sequence experiences 17 thermal pulses before ending as a $0.70492M_\odot$ white dwarf.

occurrence of DINs is confined to low-mass, low-metallicity remnants. This is true regardless the fact that our most massive remnant, $0.70492M_{\odot}$, had a very thin He-buffer ($M_{\text{Buffer}} = 5.9 \times 10^{-5}M_{\odot}$). The absence of DINs in higher mass or metallicity remnants with thin He-buffers is certainly not only because of the lower H-content that higher mass/metallicity white dwarfs *are supposed* to have. In fact, the $0.52382M_{\odot}$ $Z=0.01$ sequence does not show significant differences neither in mass nor in the values of M_{H} and M_{Buffer} from that of our reference $0.53946 M_{\odot}$ $Z=0.0001$ sequence. The key point that seems to prevent the DIN event in our more metallic sequence is related to the luminosity of the CO-core. In fact, despite the slightly lower mass and slightly higher carbon content, our $0.52382M_{\odot}$ $Z=0.01$ sequence cools significantly faster ($\approx 50\%$ at $\log T_{\text{eff}} = 4.6$) than our reference $0.53946 M_{\odot}$ $Z=0.0001$ sequence. Consequently, the core luminosity is roughly $\approx 50\%$ higher than that of the reference sequence. This, coupled to the fact that the CNO-burning shell is $\approx 25\%$ less luminous (at $\log T_{\text{eff}} = 4.6$) than the reference sequence case, makes CNO-burning stable (see section 4.3) and thus no DIN develops. The faster evolution of higher metallicity warm white dwarfs was shown in Renedo et al. (2010). It seems, then, that higher metallicity tends to prevent CNO-flashes, mostly due to a faster evolution during the warm white dwarf stage which leads to a somewhat higher gravothermal energy release in the core. In the case of our highest mass white dwarf ($\sim 0.70500M_{\odot}$), the absence of CNO flashes is related to the low luminosity of the CNO-burning shell, which is, at most (at $\log T_{\text{eff}} \sim 4.55$), $L_{\text{CNO}} \sim L_{\text{core}}$ (see section 4.3). Then, our numerical experiments, suggest that higher metallicity or masses tend to prevent the occurrence of DIN events due to the stabilizing effect of a low $L_{\text{CNO}}/L_{\text{core}}$ value (see section 4.3).

It must be noted that the final masses of our white dwarf remnants are in agreement with our present understanding of the initial-final-mass relationship for low/intermediate mass stars (Salaris et al. 2009), and thus we expect our white dwarf models to be physically sounding. In fig 7, we show the lightcurves and effective temperature evolution during the outburst for sequences with different progenitors, metallicities and final white dwarf masses.

Finally, our simulations show that DINs have characteristic properties that make them easy to recognize. First their visual lightcurve displays a sudden increase, in less than a month, of 6 to 7 magnitudes followed by slower increase in which it increases from $M_V \sim 2^m$ to its maximum of $M_V \sim -5.5^m$ in a few years ~ 2 and ~ 10 yr depending on the remnant properties. Its brightening speed just before reaching their maximum would be of 1 to 4 magnitudes per year. Also, as the star brightness increases the star should become cooler and yellowish (see Fig. 7). Such lightcurve would be probably classified as an extremely slow rising nova (Iben & MacDonald 1986). Secondly, the outburst abundances (see Table 3) of all our sequences are characterized by $\log N_{\text{H}}/N_{\text{He}} \sim -0.15 \dots 0.6$ and high N abundances of $10^{-4} - 10^{-3}$ and $\text{C} > \text{O}$, by mass fraction.

4.3 The stability of CNO-burning on white dwarfs

In this section, we will try to clarify the reasons beneath the instability of the CNO-burning shell by looking for a quan-

Figure 7. Predicted lightcurves for the DINs of remnants with different masses and descending from different progenitors. See text for details. Visual magnitudes were obtained from the predicted luminosity of the sequences and adopting the bolometric corrections derived by Flower 1996.

Figure 8. Evolution of the value of the stability parameter σ for selected white dwarf sequences. Note the significantly lower σ -values of the high mass ($0.70500M_{\odot}$) and high metallicity ($0.52382M_{\odot}$, $Z=0.01$) sequences which denote the stability of CNO-burning for those sequences. Also note the very low σ -value of our reference sequence during its second evolution of the white dwarf stage.

titative measure of the stability of H-shell burning. In this connection, we have closely followed the criterion presented by Yoon et al. (2004) and extended it to be used with mild burning shells in white dwarfs.

Yoon et al. (2004) analysed the stability of a burning shell by investigating the reaction of its mean properties under a uniform expansion of the shell and the surrounding envelope. Specifically, they defined the burning shell (where mean quantities are calculated) as those layers where the energy generation rate is $\epsilon_{\text{CNO}} > \epsilon_{\text{CNO}} \text{ at shell peak} / 0.002$. By assuming that the inner boundary of the burning shell (r_0) remains constant, neglecting the gravitational energy release of the unperturbed model, and neglecting both the lumi-

nosity of the core ($l_0 = 0$) and its perturbation ($\delta l_0 = 0$), Yoon et al. (2004) found that the temperature perturbation $\theta = \delta T/T$ follows the equation

$$\tau_{\text{th}} \dot{\theta} = \sigma \theta. \quad (1)$$

Where τ_{th} is the thermal time scale of the shell and σ is given by

$$\sigma = \frac{\epsilon_T + \kappa_T - 4 + \frac{\alpha_T}{(\alpha_P \alpha_s - 1)} (\epsilon_\rho + \alpha_s + \kappa_\rho)}{1 - \nabla_{\text{ad}} \frac{\alpha_s \alpha_T}{(\alpha_P \alpha_s - 1)}}. \quad (2)$$

Where ϵ_T , ϵ_ρ , κ_T , κ_ρ are the logarithmic derivatives of $\epsilon(T, \rho)$ and $\kappa(T, \rho)$ while α_T , α_P are the logarithmic derivatives of $\rho(T, P)$. α_s is a parameter describing the geometrical thickness of the burning shell (see Yoon et al. 2004). Then, σ is the parameter quantifying the shell instability, so that $\sigma < 0$ ($\sigma > 0$) corresponds to stable (unstable) burning.

In our case, an important shortcoming of this approach comes from the fact that the CNO-burning shell is not clearly detached from the outer pp-burning shell. Thus, the choice of the borders of the simplified burning shell is not as easy as in usual burning shells (see Yoon et al. 2004). For the present analysis we have chosen the lower boundary of the shell as the point at which $\epsilon_{\text{CNO}} = \epsilon_{\text{CNO at shell peak}}/10$, which is close to the point at which the structural effects of the burning shell start to be apparent. For the outer boundary we have chosen it to be the point closest to the shell maximum at which either $\epsilon_{\text{CNO}} = \epsilon_{\text{pp}}$ or $\epsilon_{\text{CNO}} = \epsilon_{\text{CNO at shell peak}}/10$. The other important issue comes from the fact that the core luminosity l_0 (see Yoon et al. 2004) can not be neglected in our case, due to the relative importance of the gravothermal energy release from the core as compared to the shell luminosity ($l_{\text{CNO}} = l_s - l_0$, where l_s stands for the luminosity at the outer boundary of the burning shell). Also, the perturbation of the luminosity at the inner boundary of the burning shell (δl_0) cannot be neglected either⁴. Within the scheme presented by Yoon et al. (2004) δl_0 can not be derived and, thus, we will consider it to be proportional to δl_s . It is clear that, for the reasons mentioned above, we can not expect from this approach to get a quantitative prediction of the instability of the CNO-burning shell, but we will show that its qualitative description is very useful to understand the causes beneath the shell instability.

Under the assumptions and definitions mentioned above it is easy to show that the criterion of Yoon et al. (2004) is modified so that the parameter σ quantifying the shell instability is defined as

$$\sigma = \frac{\epsilon_T x + \kappa_T y - 4y + \frac{\alpha_T}{(\alpha_P \alpha_s - 1)} (\epsilon_\rho x + \alpha_s y + \kappa_\rho y)}{1 - \nabla_{\text{ad}} \frac{\alpha_s \alpha_T}{(\alpha_P \alpha_s - 1)}}. \quad (3)$$

The main difference with the criterion presented by Yoon et al. (2004) comes from the presence of the parameters $x = (l_s - l_0)/l_s$ and $y = (\delta l_s - \delta l_0)/\delta l_s$. For the present analysis we have adopted extreme values for y ; $y = 1$ ($\delta l_0 = 0$, as in Yoon et al. (2004)) and $y = 2$ (i.e. $\delta l_0 = -\delta l_s$).

In all our sequences $\alpha_s < 0.16$ so the behaviour of the burning shell is not far from that of *thin* burning shells, where

$$\sigma_{\text{thin}} \sim \epsilon_T x + \kappa_T y - 4y + \alpha_T (\epsilon_\rho x + \kappa_\rho y). \quad (4)$$

In the absence of a core luminosity ($x = 1$) σ_{thin} , and thus instability, is dominated by ϵ_T . However, in our sequences we find the factor x to play a very important role as its values range from $x \sim 0.5$ for the $0.53946 M_\odot$ -sequence just before the flash to less than 0.2 for the $0.70500 M_\odot$ -sequence at its maximum value. An exploration of our sequences shows that the term $\epsilon_T x$ is dominant in the behaviour of σ .

In Fig. 8 we show the evolution of the parameter σ for some selected sequences. As expected, the quantitative prediction of the instability is not reproduced. However qualitatively, Fig. 8 shows that instabilities develop during the rise in the parameter σ which is caused by the increase in ϵ_T due to the cooling of the shell. However, this increase in ϵ_T is counterbalanced by the decrease in x as a consequence of the dimming of the shell. The interplay between these two main factors is crucial for the development of the instability. Diffusion leads to an increase of the CNO-burning shell power, which increases x and might trigger the flash. If, by the time diffusion starts to change the H-content at the H-burning layers the shell is already very dim H-burning remains stable and no DIN develops. The existence of a thicker He-buffer delays the effect of diffusion and thus, if the buffer is thick enough H-burning remains stable during the white dwarf cooling. From Fig. 8 we can also understand why higher mass sequences ($M \sim 0.70500 M_\odot$) do not undergo DIN events despite the very thin helium buffers. The reason is that burning shells are too dim as compared with the core luminosity and, thus, very low x values render H-burning stable. In the case of the high metallicity ($Z=0.01$) $0.52382 M_\odot$ -sequence discussed in previous sections, its faster cooling (than our reference $Z=0.0001$ sequences of similar mass) is tied to a higher core luminosity which makes CNO-burning stable.

Thus, our analysis suggests that CNO-flashes depend on the intensity of the CNO-burning shell (compared to the core luminosity, i.e. x) and its temperature (i.e. ϵ_T). Both factors depend on diffusion velocities, which mixes H into deeper, hotter, layers increasing the CNO-burning power, and the thickness of the He-buffer which delays the contact between C and H. Finally, the relative intensity of the CNO-burning shell compared to the core luminosity depends on the mass and (progenitor) metallicity of the white dwarf, a fact that seems to prevent DIN events in higher mass and metallicity remnants.

4.4 Effect of extramixing in the CNO-flash driven convective zone

In the interests of completeness we have also analysed the impact of extramixing in the flash-driven convective zone. In this connection, we have recalculated the DIN event for our reference sequence including extramixing beyond convective boundaries during the flash. This was done within the picture developed by Herwig et al. (1997) of an exponentially decaying overshooting (OV) with $f = 0.016$ (see Herwig et al. 1997 for a definition). It is worth noting that, although the physical picture behind this prescription might not be correct, it can be considered as an effective way to include extramixing processes that take place at convective boundaries (e.g. gravity waves; see Herwig et al. 2007).

The main consequence of the inclusion of OV during

⁴ Note that this is also true for those cases in which $l_0 \sim 0$.

the development of the CNO-flash convective zone is that H is dragged deeper, into hotter regions of the star. This enhances the CNO-burning luminosity during the flash, which can be as high as $L_{\text{CNO}} \sim 10^{10} L_{\odot}$, significantly higher than the value of $L_{\text{CNO}} \sim 10^7 L_{\odot}$ predicted by no-OV sequences. Also, due to the fact that the convective zone reaches deeper during the flash, much more material from the N-rich He-buffer (and even from the C-rich intershell) is dragged to the surface during the outburst. As a consequence the surface abundances during the outburst are significantly enhanced in He and N (see Table 3). Also, surface C and O are strongly increased to $\sim 10^{-3}$ (by mass fractions), as compared with the $10^{-5} - 10^{-6}$ resulting from the case when OV is neglected. It is worth mentioning that the increase in C and O would be higher if the intershell abundance of the model is richer in C and O (see section 5.2 and Table 3). Also, as the CNO energy release is orders of magnitude higher when OV is considered, the event is more violent, reaching the giant stage in less than a year and showing a much steeper outburst lightcurve (see Table 2). Also, when OV is included the duration of the giant stage (τ_3 , Table 2) is also enhanced, being of the order of $\sim 10^4$ yr. This is because much more H is consumed in this case and consequently much more energy is released, allowing for a longer giant stage. Also as a consequence of this higher H-burning, the amount of H remaining in the star by the time it reenters the white dwarf stage is about $M_H \sim 10^{-5} M_{\odot}$, six times smaller than in the no-OV case ($M_H \sim 5.7 \times 10^{-5} M_{\odot}$)⁵

4.5 Comparison with Iben & MacDonald 1986

In this section we compare our results with those of the DIN calculated by Iben & MacDonald (1986). In Table 2 we show the main characteristics of our simulations together with those extracted from Iben & MacDonald (1986). An examination of Iben & MacDonald (1986) results show that all the predicted quantities fall within the range predicted by our simulations. In particular, it is worth noting that the time, luminosity and temperature at which the nova takes place in the simulation of Iben & MacDonald (1986; IM86) are very similar to those of our sequence of similar metallicity (although different mass). The same is true for the abundances of He and H during the outburst. In view of the many numerical and physical differences between Iben & MacDonald (1986) and our simulations, we consider the similarities of both results as a strong indication for the robustness of the results and the feasibility of the scenario. In particular, we feel confident that the results presented in Tables 2 and 3 reflect the main characteristics of DIN outbursts.

Regarding the work by Iben & MacDonald (1986) some comments need to be done. The authors conclude that if the He-buffer thickness is smaller than a critical value given by $M_{\text{Buffer}}^{\text{CRIT}} \sim \Delta M_H / 10$, where ΔM_H stands for the increase of the H-free core during the interpulse phase on the AGB, then a DIN occurs. This conclusion has been recently used by Lawlor & MacDonald (2006) to conclude that DINs can not occur in white dwarfs descending from

progenitors of masses lower than $3M_{\odot}$. This result is completely at variance with the results presented in the previous sections where all DINs come from low mass progenitors. However, it should be mentioned that the condition $M_{\text{Buffer}}^{\text{CRIT}} \sim \Delta M_H / 10$ seems to be based on a single sequence, and thus it may be wrong to extrapolate it to remnants of different masses. During the present study we have not found such "critical value" to be fulfilled. In fact, in our $0.85 M_{\odot}$ sequences we find the frontier between the development or not of a diffusion nova to take place somewhere between our $0.54148 M_{\odot}$ ($M_{\text{Buffer}} = 2.3 \times 10^{-3} M_{\odot}$) and our $0.54148 M_{\odot}$ ($M_{\text{Buffer}} = 2.06 \times 10^{-3} M_{\odot}$) remnant. For these sequences, the increase of the H-free core between thermal pulses is $\Delta M_H = 0.0101 M_{\odot}$, very similar to Iben & MacDonald (1986) value. Then, the critical He-buffer thickness is $M_{\text{Buffer}}^{\text{CRIT}} \sim 2 \times 10^{-3} \sim \Delta M_H / 5$. This is two times larger than suggested by Iben & MacDonald (1986). On the other hand, for our $1.8 M_{\odot}$ progenitor we find that while our $0.6236 M_{\odot}$ ($M_{\text{Buffer}} = 7.5 \times 10^{-5} M_{\odot}$) white dwarf remnant does experience a CNO-flash, our slightly more massive remnant of $0.6239 M_{\odot}$ ($M_{\text{Buffer}} = 3 \times 10^{-4} M_{\odot}$) does not. Then, as the increase of the H-free Core for the $1.8 M_{\odot}$ sequence during the fifth thermal pulse is $\Delta M_H = 0.009$, then the critical He-buffer thickness is $M_{\text{Buffer}}^{\text{CRIT}} \sim \Delta M_H / \alpha$ with α a number between 30 and 120. Finally, let us mention that when we followed the AGB evolution of our $1.8 M_{\odot}$ sequence up to 17^{th} thermal pulse, the growth of the H-free core during the interpulse phases is $\Delta M_H = 0.0059 M_{\odot}$. For the white dwarf remnants created from this progenitor, even in the case with the thinner He-buffer, $0.70492 M_{\odot}$ ($M_{\text{Buffer}} = 5.9 \times 10^{-5} M_{\odot}$), we did not obtain a DIN. Even though in this case $M_{\text{Buffer}} = \Delta M_H / 100$, no DIN developed. This is in line with our analysis of Section 4.3 that suggests that for these white dwarf masses DIN events will not develop, regardless of the He-buffer mass. Then, we conclude that the previously mentioned critical He-buffer mass for the development of a DIN is misleading. As mentioned in section 4.3 it is clear that the He-buffer thickness is not the only ingredient that determines whether a DIN will occur.

Finally, Iben & MacDonald (1986) speculate⁶ that DINs might be recurrent. As mentioned in the introduction, the occurrence of recurrent DIN episodes has been invoked (D'Antona & Mazzitelli 1990) as a possible mechanism to explain the existence of DA white dwarfs with thin H-envelopes (as those inferred by some asteroseismological studies; e.g. Castanheira & Kepler 2009). Our computation of the aftermath of the DIN, shows that the star evolves much faster during its second cooling stage as a white dwarf and thus, diffusion has no time to significantly alter the chemical profiles of the inner regions of the white dwarf. As a consequence, H-burning during the second white dwarf evolution remains stable and no recurrent DIN events can develop.

⁵ Note that this factor corresponds also to the difference between the duration of the giant stage in the no-OV case, $\tau_3 = 260$ yr, and the OV case $\tau_3 = 1367$ yr.

⁶ Due to numerical difficulties they stopped their simulation once the star returned back to a giant configuration.

5 POSSIBLE OBSERVATIONAL COUNTERPARTS

5.1 Speculations on the origin of CK Vul

In the previous sections we have presented the predictions of the DIN scenario. As these events have been suggested to look like “very slow novae” it seems natural to compare their predictions with some of those objects. The most famous and enigmatic one is Hevelius nova CK Vul (Shara et al. 1985). Here, we will compare the predictions of the DIN with observations from CK Vul and with the predictions of the best available scenario, the very late thermal pulse (VLTP; Harrison 1996, Evans et al. 2002 and Hajduk et al. 2007).

5.1.0.1 Surface composition, H-abundance One of the most remarkable difference between VLTP models and observations of CK Vul come from the significant H emission detected in the ejected material of CK Vul, in contrast with the extreme H-deficiency detected in the ejected material of the two bonafide VLTP objects; V4334 Sgr and V605 Aql (Hajduk et al. 2007). In this connection, the DIN scenario predicts a high H-content in the envelope during the outburst and, thus of the ejected material (see Table 3), contrary to the predictions of the VLTP scenario (see Miller Bertolami & Althaus 2007). Also it is worth noting that the most abundant CNO element predicted by the DIN scenario is N, which is clearly detected in CK Vul surrounding material (Hajduk et al. 2007).

5.1.0.2 Absence of an old planetary nebula From the low dust emission surrounding CK Vul, Hajduk et al. (2007) conclude that CK Vul must be an evolved object $10^5 - 10^6$ yr older than the last time it experienced steady high mass loss (e.g. on the TP-AGB). This time is orders of magnitude longer than the time from the departure of the TP-AGB to a VLTP ($\sim 10^4$ yr). In fact both V4334 Sgr and V605 Aql show old planetary nebulae surrounding the new ejected material (Kimeswenger et al. 2007). On the contrary, the DIN scenario predicts a much longer timescale between the cessation of high mass loss and the time of the CNO-flash. As shown in Table 2, this timescale is of the order of $10^6 - 10^7$ yr, in closer agreement with the observations of CK Vul.

5.1.0.3 Ejected Mass Due to the fact that the expanding layers in a DIN episode are those above the region of the CNO-flash, DIN models have a very stringent upper limit to the mass that can be expelled during the outburst. As an example, the location of the H-flash in our reference sequence is $\lesssim 10^{-3} M_\odot$ below the surface and the expanded envelope once the star is back on the AGB is of about $\sim 10^{-4} M_\odot$. Thus, we can safely conclude that the ejected mass in the DIN scenario will be of $\sim 10^{-4} M_\odot$ —and surely smaller than $\sim 10^{-3} M_\odot$. These values are within the inferred masses for the ejected material in CK Vul, which is of $10^{-5} M_\odot - 5 \times 10^{-2} M_\odot$ depending on the assumptions (Hajduk et al. 2007).

5.1.0.4 Outburst lightcurve CK Vul was discovered at its maximum brightness on the 20th of June of 1670 as 3rd magnitude star. Although no description of the out-

burst lightcurve exist, Shara et al. (1985) conclude that it is very unlikely that the star was visible in the previous season. Thus, only a lower limit to the brightness speed of ~ 2 magnitudes per year can be established. This limit is within the values predicted by the DIN scenario (see Table 2). After reaching maximum brightness it faded and recovered twice before finally disappearing from view. These fadings are remarkably similar to those observed in born again AGB stars (V605 Aql; Duerbeck et al. 2002 and V4334 Sgr; Duerbeck et al. 2000) and RCrB stars (Clayton 1996). In fact, this particular lightcurve was one of the main arguments to link CK Vul to the VLTP scenario (Harrison 1996, Evans et al. 2002). RCrB-like fading are usually associated with carbon dust so one should wonder if such fading episodes could take place in atmospheres which are not C-rich, as those predicted by our DIN simulations (see Table 2). In this connection, we find suggestive that there is one “Hot RCrB”, MV Sgr (De Marco et al. 2002), which has a carbon and nitrogen composition very similar ($C \sim 5 \times 10^{-4}$ and $N \sim 9 \times 10^{-4}$) to those predicted by the DIN scenario ($N > C > O$ and $N \sim 10^{-3} - 10^{-4}$, see Table 3), although MV Sgr shows a much stronger He-enrichment. We consider that MV Sgr suggests that DIN events might also display the fadings observed in RCrB like lightcurves, although we consider this just an speculation and should be analysed in detail. From these considerations we conclude that our present understanding of the DIN-scenario is not in contradiction with CK Vul eruption lightcurve.

5.1.0.5 Maximum brightness The maximum brightness is the main discrepancy between observations and models (both for DIN or VLTP models). While observations of CK Vul suggest at the preferred distance $M_V^{\text{CK Vul}} \sim -8$, DIN models predict significantly lower values of $M_V^{\text{DIN}} \sim -5.5$. It is worth noting, however that this is even worst for VLTP models, in which fast-VLTP sequences predict $M_V^{\text{VLTP}} \sim -4$ (according to the predicted luminosities in Miller Bertolami & Althaus 2007).

5.1.0.6 Actual luminosity of CK Vul One of the main discrepancies between inferences from CK Vul and both DIN and VLTP scenarios comes from the radio emission. In fact, from the radio emission detected by Hajduk et al. (2007) these authors derive a very low luminosity of $\sim L_\odot$ for the ionizing object. This is done by considering that hydrogen is ionized by the photons emitted by the central object above the Lyman limit. Neither the DIN nor VLTP events can account such very low luminosities only 330 yr after the outburst. However, it is worth noting that such very low luminosity is derived from the assumption that the temperature of the central object is close to the effective temperature at which the number of ionizing photons is maximum. From the data presented by Hajduk et al. (2007) and adopting the expression from Wilcots (1994),

$$F_e = 1.761 \times 10^{48} \times a(\nu, T_e) \times \nu^{0.1} \times T_e^{-0.45} \times S \times D^2, \quad (5)$$

we derive that the number of ionizing photons is $N_\gamma \sim 4 \times 10^{43} \text{ s}^{-1}$. As the number of ionizing photons is steeply dependent on the effective temperature of the star, such number of photons can also be attained by a star of $T_{\text{eff}} \sim 10000 \text{ K}$ and $L \sim 10000 L_\odot$. These values put the central object back in the AGB region of the HR-diagram. Hence we

are tempted to speculate that the radio emission could be compatible with an object reheating back from the second stage in the AGB and thus, compatible with both VLTP and DIN scenarios. However, increasing the luminosity of the star should increase the IR-flux from the obscuring material (Evans et al. 2002). One may thus wonder if the IR-flux would be much higher than the observational limits (e.g. $S_{12} \sim \text{mJy}$; Hajduk et al. 2007). Some rough numbers show that this would be strongly dependent on the geometrical and physical assumptions on the obscuring material. For example, if we assume the star being obscured by a circumstellar shell located at $r \sim 30\text{AU}$ (and assumed to behave as a blackbody), we obtain a shell temperature of $T_{\text{dust}} \approx 720\text{K}$ and a flux of $S_{12} \sim 1000\text{ Jy}$, several orders of magnitude above the observational upper limit (Hajduk et al. 2007). On the contrary if the star is obscured by the presence of a pre-existing edge-on disk ($r_{\text{inner}} = 1\text{AU}$, $r_{\text{outer}} = 60\text{ AU}$ and height $h = 1\text{AU}$), as suggested by the ejection almost perpendicular to the line of sight, then the IR flux would be much lower. Indeed, by assuming a classical temperature profile ($T \propto r^{-3/4}$; Natta 1993) and a black body behaviour we (roughly) estimate $S_{12} \sim 25\text{ mJy}$, much closer to the observational constraints (Hajduk et al. 2007).

We conclude that, if CK Vul is actually obscured by a thick disk, the radio emission could be explained by a cool reborn giant star ($T_{\text{eff}} \sim 10000\text{K}$ and $L \sim 10000L_{\odot}$) without an strong IR emission. This would help to reconcile the predictions of both VLTP and DIN scenarios with the observed properties of CK Vul. Then, a detailed modeling of the dust surrounding CK Vul seems to be key in order to reject a possible luminous cool central star as the present state for CK Vul.

5.2 Possible connection with PB8

As mentioned in Section 4.4, the inclusion of extramixing processes at the boundaries of the CNO-flash driven convective zone leads to outburst abundances rich in He, H and N (see Table 3). Also, the inclusion of extramixing processes leads to a more violent flash and to an increase in the time spent as a giant (τ_3 ; see Table 2) after the DIN event. During this short giant stage the reactivation of AGB winds is expected. Depending on the amount of mass lost during this stage, it could be possible that the new ejected material might form a new young planetary nebula once the star begins to contract and heat towards the second white dwarf phase. Such young planetary nebula would show very low dynamical ages and, together with its central star, a very atypical He, H and N rich composition. PB8 has been recently shown to have (qualitatively) similar characteristics (Todt et al. 2010, García-Rojas et al. 2009), namely low dynamical age of a few thousand years and a He-, H- and N-rich composition. Specifically, the central star of PB8 has been proposed as the prototype of [WN/WC], a new class of CSPN. In particular, the surface abundances of PB8-CSPN have been derived, by Todt et al. (2010), to be $[\text{H}/\text{He}/\text{C}/\text{N}/\text{O}] = [40/55/1.3/2/1.3]$. These abundances can be accounted by our DIN sequences that include extramixing processes at convective boundaries—see Table 3. Indeed, as mentioned in Section 4.4, when overshooting is included at the CNO-flash convective zone, convection drags material from deeper layers of the white dwarf, reaching the upper

layers of the C-rich intershell. Thus, the C and O surface abundances after a DIN event will be strongly dependent on the intershell composition of the star when departing from the AGB. In fact, if intershell abundances are assumed to be similar to those of PG1159 stars (see Werner & Herwig 2006) much higher C and O abundances are obtained after a recalculation of the DIN event (see Table 3). In fact, the abundances obtained in this case are in good qualitative agreement with those derived by Todt et al. (2010) for PB8-CSPN (i.e. $\text{He} \gtrsim \text{H} > \text{N} \gtrsim \text{C} \sim \text{O}$). Also, the dynamical age derived by Todt et al. (2010), $\tau = 2600\text{ yr}$, is qualitatively similar to the giant phase duration of this sequence ($\tau_3 \sim 1600\text{ yr}$). Taking into account that our simulations correspond to a single, arbitrarily chosen sequence, we find the similarities with the observed properties of PB8 to be remarkable. Further exploration of this possible explanation for PB8 seems natural.

6 FINAL REMARKS

We have performed a detailed exploration of the diffusion-induced nova scenario (DIN) originally proposed by Iben & MacDonald (1986). Our calculations represent a significant improvement in our understanding of CNO-flashes in warm white dwarfs.

Our main results can be summarized as follows:

- We have identified a definite scenario leading to the formation of DA white dwarfs with thin He-buffers. Such white dwarfs are naturally formed in low-mass stars, that do not experience third dredge up during the TP-AGB, and suffer from either an AFTP or a LTP.
- We have explored the parameter space of the DIN scenario and shown that there is a range of values of M_{\star} , Z_{ZAMS} and He-buffer masses for which DIN occur in physically sounding white dwarf models. Our results suggest that DINs take place in white dwarfs with $M_{\star} \lesssim 0.6$ and $Z_{\text{ZAMS}} \lesssim 0.001$ and thin He-buffers—as those provided by the scenario described above.
- Our simulations provide a very detailed description of the events before, during and after the DIN event. In particular, our results show that DIN events are not recurrent as previously speculated. Thus, DINs do not form H-deficient white dwarfs, nor DA white dwarfs with thin H-envelopes.
- We have qualitatively described the mechanism by which the CNO-shell becomes unstable. Our analysis shows that the occurrence of CNO-flashes depends strongly on the intensity of the CNO-burning shell (as compared to the core luminosity), and its temperature. This seems to be in agreement with the fact that only our sequences with $M_{\star} \lesssim 0.6$ and $Z_{\text{ZAMS}} \lesssim 0.001$ and thin He-buffers experienced DIN events.
- Regarding the criterion presented by Iben & MacDonald (1986) for the occurrence of DIN events, we find that such criterion is misleading as the He-buffer mass is not the only parameter that determines whether a DIN event will take place or not. In particular, for more massive remnants our simulations do not predict DIN for any possible He-buffer masses.
- Our simulations provide a very detailed description of the expected surface abundances and lightcurves during the

outbursts. In particular we find that typical lightcurves display a maximum of $M_V \sim -5.5$, a brightness speed of a few magnitudes per year, and a mild He- and N- enrichment; with $N \sim 10^{-4} - 10^{-3}$ by mass fraction and $\log N_H/N_{He} \sim -0.15...0.6$. Also, in all our sequences we find surfaces abundances with $N > C > O$ by mass fraction.

- We find that the inclusion of extramixing events at the boundaries of the CNO-flash driven convective zone leads to higher He, N, C and O abundances than in the case in which no extramixing is considered. Relative surface CNO abundances in these cases are $N > C \gtrsim O$ (by mass fractions), although the precise values will be strongly dependent on the C and O composition of the He-, C- and O- rich inter-shell.

- Finally, with the aid of our numerical simulations, we have discussed the possibility that Hevelius nova CK Vul and PB8-CSPN could be observational counterparts of DIN events.

For CK Vul we find that despite discrepancies with observations the DIN scenario offers a possible explanation for CK Vul which is as good as the best available explanation to date (the VLTP scenario). In particular the DIN scenario can easily explain the absence of and old planetary nebulae surrounding CK Vul and the presence of H in the ejected material, which cannot be understood easily within the VLTP scenario. Moreover, we suggest that the radio and IR emission from CK Vul (Hajduk et al. 2007) could be explained if the star is assumed to be in its giant stage and surrounded by a pre-existing dust disk. Such reinterpretation of the observations would reconcile them with both the VLTP and DIN scenarios. A further exploration of this possibility seems desirable.

Regarding PB8, our simulations show that the atypical abundances observed in PB8 (Todt et al. 2010) and the low dynamical age of its nebula (García-Rojas et al. 2009) could be qualitatively understood within the DIN scenario if extramixing is allowed at the boundaries of the CNO-flash convective zone.

Table 2. Outburst properties of the DINs studied in this work. Unless stated otherwise, all sequences come from ZAMS progenitors with $Z = 0.0001$. Timescales are defined as follows; cooling time at the moment of the CNO-flash (τ_1), expansion time from the maximum energy release to the giant stage at $\log T_{\text{eff}} = 3.9$ (τ_2), duration of the cool ($\log T_{\text{eff}} < 4$) giant stage (τ_3) and contraction time needed to reach the pre-outburst luminosity (τ_4). † These remnants were obtained by reducing the mass lost during the final AGB thermal pulse from that predicted by standard AGB wind prescriptions. ‡ This remnant was obtained by applying an artificially high wind during the fifth thermal pulse. \wr These DINs were obtained from the $0.53946M_{\odot}$ sequence by including overshooting (OV) in the convective zone generated during the CNO-flash. * In this case the intershell composition of the remnant was modified to resemble the C- and O- rich surface abundances of PG1159 stars. IM86 indicates the sequence computed by Iben & MacDonald (Iben & MacDonald 1986).
